METHOD AND APPARATUS FOR REDUCING FLICKER EFFECTS FROM
DISCHARGE LAMPS DURING PIPELINED DIGITAL VIDEO CAPTURE

BACKGROUND

Field of the Invention

The present invention relates to the field of use of digital video capture. More particularly, the present invention relates to method and apparatus for eliminating flicker effects from discharge lamps during pipelined digital video capture.

Description of Related Art

Digital cameras are currently being used in many applications, including both still image and video acquisition. To acquire images, digital cameras utilize a sensor array made up of an arranged pattern of photodiodes (i.e., light sensitive diodes, or, photosensors). Each photodiode measures the amount of light it receives by storing a corresponding amount of charge on an integrated capacitor. The amount of charge stored by each photodiode is then converted into a digital value by an analog-to-digital converter such that all the digital values, after being converted and reassembled into a particular array, can be processed to arrive at a digital image.

Typically, the photosensor array is exposed to the scene to be captured through the use of either a mechanical or electronic shutter that allows either (1) light to fall upon the photosensor array, or (2) charge to accumulate on each photosensor in the array, respectively. The photosensor array can either capture the charge in a row-by-row fashion as in the latter case, or, alternatively, in the former case, the image can be captured as a whole (i.e., the photosensor array is exposed to a light source all at once). The processing of the charges which are stored on each of the photosensors is then performed either in a row-by-row fashion, or in a pixel-by-pixel fashion. Images captured in this row by row fashion is termed to be captured in a "pipelined" mode of operation. For video image capture

applications, a series of frames (i.e., images) are captured similar to the manner above.

As digital cameras are positioned to replace traditional film-based cameras, they must be capable of operating under a variety of lighting situations. For example, digital cameras must be able to capture videos of scenes which are illuminated by sunlight, if outdoors, or which are illuminated by incandescent or fluorescent lights, if indoors.

However, when capturing a sequence of frames under an environment lighted by a discharge lamp (e.g., a fluorescent light), the digital video will contain artifacts due to the fact that the discharge lamp can vary in intensity and color temperature as a function of time. Thus, discharge lamps such as fluorescent lights does not offer a constant intensity of light but instead offers an intensity which, if measured and plotted on a chart, resembles a full wave rectified sine wave.

Figure 1 shows an example of the intensity of fluorescent lighting as it varies over time, where the Y-axis represents the intensity of the light sensed by the photodiode, and the X-axis represents the passage of time. As can be seen by Figure 1, the intensity of the light generated by fluorescent lighting (and thus sensed by the photodiode) is periodic and resembles the absolute values of a sine wave. As the variation of the intensity is a function of time, a video stream that is captured in this lighting will include a potentially considerable amount of variation in the quality of the captured video as the capture is also a function of time,

The problem is also compounded in the fact that the variation in the intensity of the fluorescent lighting is different in different parts of the world as some countries use a 60 Hz alternating current (AC) power system and other countries use a 50 Hz AC power system. For example, the United States uses an AC power system which oscillates at 60 Hz. Thus, depending on the country in which the digital camera is used, the frame capture rate

will have to be adjusted such that the frame capture rate is a function of the operating cycle of the power supply.

One approach that allows a digital camera to function under the fluorescent lighting of different power systems is to have the user enter a code designating the country in which the digital camera will be used. The camera would then adjust the frame capture rate according to the operating frequency of the country. The camera would maintain a list of correspondences between the regions in which it is currently operating and also what power system is functional in that region. Also, this approach will require the user to input a code every time a user entered a region with a different power system. Thus, this approach would require that the user manually enter the user's current location.

A second approach would be to incorporate a system into the camera itself, such as a global positioning system (GPS), which would allow the camera to be "self-aware" as to which geographic location it is in and thus automatically sets the camera's internal systems accordingly. However, this approach would require additional circuitry which would place additional power and cost requirements into the digital camera.

Yet another approach would be to include circuitry to have the camera automatically recognize the power system in which it is currently operating by having the user plug the camera into the power system of the country. For example, when a user reaches a certain location or a new region, the user would simply plug the camera into a wall outlet to allow the circuitry of a digital camera to register the operating cycle of the power system. However, this approach is also not recommended as different regions around the world usually have different configurations of wall sockets and connectors on those sockets such that the user would have to carry along a set of adapters, which could number into the tens or hundreds, to be sure that the user can plug the digital camera into the power system.

It would be preferable to have a system which eliminates the effects of using fluorescent lighting that

does not require user intervention or increased cost and power requirements on the camera itself.

SUMMARY

What is disclosed is a method having the first step of setting a first frame rate. Then, setting a capture integration period to a first integration period, and capturing a set of frames under an illumination source with a first frequency. Thereafter, determining the first frequency of the illumination. What is also disclosed is an apparatus for performing the above method having an image sensor and a capture control unit coupled to the image sensor.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 is a plot of the light intensity from a discharge lamp measured over time.

Figure 2 illustrates the sampling of image data over time using a pipelined image sensor.

Figure 3 is a plot of row averaged captured image data over time for a particular captured image.

Figure 4 is a plot of the magnitude of captured illumination, including image data, over time.

Figure 5 is a plot of integration time versus flicker amplitude for two light sources at different frequencies.

Figure 6 is a plot of the signal shown in Figure 4 after a Fourier transform.

Figure 7 is an image capture system configured according to one embodiment of the present invention which includes a flicker detector.

Figure 8 is a flow diagram of the operation of the image capture system including the flicker detector.

DETAILED DESCRIPTION OF THE INVENTION

The present invention provides a method and apparatus for reducing the effects of flicker from discharge lamps in a captured video stream. For purposes of

explanation, specific embodiments are set forth to provide a thorough understanding of the present invention. However, it will be understood by one skilled in the art, from reading this disclosure, that the invention may be practiced without these details. Further, although the present invention is described through the use of a CMOS image sensor, most, if not all, aspects of the invention apply to image sensors in general. Moreover, well-known elements, devices, process steps and the like are not set forth in detail in order to avoid obscuring the present invention.

As the intensity and color value output from a fluorescent lamp varies in a sinusoidal, therefore periodic fashion, due to the applied AC voltage, the present invention utilizes the image sensor to sample the overall illumination to detect whether the system operating in a 50Hz, 60Hz or incandescent light situation. Then, integration is performed by the image sensor under different constraints based on the detected light frequency. The timing allows the photosensor array to capture each frame at approximately the same time in the cycle of the oscillation of the light intensity received from the fluorescent lamp.

Figure 2 is a diagram of the sampling of image data over time using a pipelined image sensor. The frame capture begins at time 0 when a frame capture signal is asserted. During capture, each row receives a RESET signal which allows the row to begin integration. In one embodiment, all rows have an integration time "t" which is constant for each row. After integration time t, a line readout signal is provided to the particular row of the sensor to read out the integrated value which represents the image data for that particular row for each pixel in that row. In the example shown in Figure 2, the image sensor contains 480 lines of resolution, which means that there are 480 rows of pixel sensors. As soon as the integration time period has elapsed, each row of pixel sensor values are read out for processing. After the last row of pixel sensor values are read out, the next frame is captured by having the first row of the image sensor receiving a RESET command. As the image sensor operates in a pipelined mode, as soon as

the last row of the image sensor has received a RESET command to initiate capture, a RESET command to initiate capture for the next, which is the first row of the image sensor, is automatically sent. As shown by Figure 2, the sampling occurs in the time axis ("X" axis in the diagram), but what is being sampled varies by the row ("Y" axis in the diagram), so the illumination data is intermixed with actual image data.

Figure 3 is a plot of captured image data for each row which has been averaged (i.e., where the pixel values of each row have been averaged), over time for a particular captured image. As discussed below, the image data is averaged for each row so as to mitigate the effects of choosing a particular column of pixel data to analyze. For example, if the last column of pixel values on the right hand side of the image is selected for analysis, it would yield a very different result, than if the column of pixel data came from the center of the image. By averaging the image data for each row, the actual changes in values due to the "picture" contained in the image has less effect on the actual data which is used for analysis of the illumination of the image.

Figure 4 is a plot of the magnitude of captures illumination that is output by the image sensor over time after it has been converted by an analog-to-digital converter. The output illumination data is intermixed in the image data, and, in Figure 4, both of them are plotted over time. The illumination of light represents the row average of each row as it is being captured. The Y-axis is in units of the output of the analog to digital converter, where, in this embodiment, is an integer from 0 to 255, representing an 8-bit analog-to-digital conversion of the output of the image sensor. In order to determine the frequency of the illumination amplitude oscillation due to florescent lighting in the captured image data, the image data is operated on by a Fourier transform. This is further discussed with Figure 6, below.

In order to eliminate the capture of the effects of illumination which has oscillating amplitude in image

data, it should be noted that the power amplitude Fourier transform of a pulse wave form resembles the absolute value of the sinc function (i.e., $|\sin(X)/X|$) and in particular, this function contains zeros. As the zeros correspond to the illumination flicker, if the integration time is set to the values which correspond to the values at which point the power amplitude of the Fourier transform is equal to zero, then illumination flicker can be eliminated. Thus, depending on whether images are captured under a 50 or 60Hz illumination, integration time can be set at particular values to eliminate the flicker effects caused by the oscillating level of illumination. In helping to determine the oscillation frequency of the light source, it is necessary that the integration time is chosen so that the amplitude of the effect caused by either the 50Hz or the 60Hz light source would be similar.

As can be seen by Figure 5, there are several places where the plot of the amplitude of the 60Hz signal wave form is equal to the plot of the amplitude of the 50Hz signal wave form. In one embodiment, the integration time is set to 0.0132 seconds. The reason why the integration time is set to a value which will result in similar amplitudes for the 50 and 60Hz frequency is so that the presence of illumination at one frequency can be easily detected. For example, if the integration time was set to 0.017 seconds, where the amplitude of the 50Hz signal is much greater than the amplitude of the 60Hz signal, then it would be very hard to detect the effect caused by the 60 Hz signal as it is very close to zero. Table 1 contains a sample list of integration times suitable for determining the oscillation frequency of the light source.

As discussed above for Figure 4, the effect of the oscillating illumination of the captured image is contained in the image data. To separate out the illumination effects, a fast-Fourier-transform (FFT) function is performed on the image data to determine the frequency of oscillation, if any, of the illumination.

Figure 6 is a plot of the data shown in Figure 4 after a FFT, assuming that the illumination during the capture of the image data in Figure 4 is due to a 60Hz light source. As can be seen in Figure 6, there is a "spike" that appears at 120 Hz as the illumination data indicates that a 60Hz power line source was detected. It is to be noted that the spike appears at 120Hz as the illumination fluctuates at twice the line frequency, which in this case is 60Hz (i.e., the illumination charges with both the "positive" and "negative" portion of the 60Hz cycle).

Figure 7 is a block diagram of an image capture and processing system configured in accordance with one embodiment of the present invention with a photosensor array 100, a buffer and processing unit 102, an analog-to-digital (A/D) unit 104, a capture control unit 106, a FFT unit 108, and a detector unit 110. Buffer and processing unit 102, FFT 108, and detection unit 110 make up a flicker detector 112.

Photosensor array 100 is operated in a pipelined mode, which, as discussed above, means that each row of photosensor array 100 is integrated in a row by row basis. The output of photosensor array 100 is fed into A/D unit 104. Specifically, photosensor array 100 outputs the capture charges, based on the control signals sent by capture control unit 106, to A/D unit 104 for processing. Capture control unit 106 is controlled in turn by flicker detector 112. Specifically, once buffer and processing unit 102 receives the captured image data from A/D unit 104, it performs any processing that is necessary and then sends the results to FFT unit 108. FFT unit 108 then operates on the results that are received from buffer and processing unit 102 and then sends the resulting data to detector unit 110.

Detector unit 110 then outputs a signal to capture control unit 106 to indicate the lighting condition under which the camera is operating. As described above, buffer and processing unit 102, FFT unit 108, and detector unit 110 make up flicker detector 112.

In one embodiment, at the same time that buffer and processing unit 102 receives data from A/D unit 104, buffer and processing unit 102 provides the same information to post processing and storage units (not shown). The post processing and storage units can include units for providing further image processing, such as compression or image enhancement. The storage component in the post processing and storage units can be any media suited for storing digital data. In one embodiment, the storage unit is a non-volatile memory such as magnetic media. However, any storage facility used for storing digital data will be suited, whether it is volatile or non-volatile memory. In other embodiments, the functions provided by flicker detector 112 can be implemented together with the functions provided by the post processing and storage units. In addition, it should be noted that the functions of flicker detector 112, along with the functions provided with the processing and storage units, can be provided by a general purpose computer that provides the general purpose processor and storage units as described above. Thus, the actual implementation of the processing and storage units described in Figure 7 can be implemented in a variety of solutions, whether they are in hardware or software.

Figure 8 is a flowchart of one embodiment of the operation of the present invention. The process begins with step 300, during which capture control unit 106 is set to capture one or more frames using photosensor array 100 at a particular frame rate. The minimum frame rate is dependent on the total number of data samples to be acquired. The sampling rate and total number of samples are selected to avoid undersampling. The exact sampling requirements may be varied over an almost limitless range providing Nyquist resolution is maintained. In one embodiment, the frame rate is set to recover at least 120Hz, which is double the

frequency rate of any encounterable florescent light (i.e., double the highest encounterable power supply line frequency, which is 60Hz). This is to ensure that the changes in illumination would be captured as the capture frequency has to be high enough to avoid Nyquist effects due to undersampling.

Undersampling is not usually a problem, as each line in photo sensor array 100 captures one "sample" of illumination. For example, assuming typical frame rates of 15 frames per second, even if photo sensor array 100 only has 16 lines of resolution, there would be enough samples to satisfy Nyquist resolution of 240 Hz to recover 120 Hz.

In step 302, the integration time is set to approximately 13.2 milliseconds. As described above, this integration time has been chosen to allow capture of illumination from either the 60Hz or 50Hz light source to be at the same amplitude. Operation then proceeds with step 304.

In step 304, one or more frames are captured by photosensor array 100 at the integration time set by capture control unit 106 as in step 302 (i.e., 13.2 milliseconds). Specifically, the integration time used for each row is 13.2 milliseconds.

In step 306, the captured image data for each row of the frame is horizontal averaged. As described above, the averaging of the image data for each pixel in a row decreases the effects of having a dark object or a light object in the scene so that any illumination fluctuations caused by a florescent light may be detected more easily. For example, if the images being captured are completely uniform in image data, such as a completely white picture, then any changes in illumination may be easily detected. Without averaging, choosing a random column pixel causes unpredictable results depending on which column of photosensor array 100 is chosen. The resulting data would be similar to the data in Figure 4.

In step 308, if more than one frame has been captured, and, assuming that the interframe gap is equal to zero (i.e., frames are captured successively without a

pause), the horizontally averaged image data can be "stitched" together to form a continuous series of horizontally averaged image data. Operation will then continue with step 310.

In step 310, a fast-Fourier-transform (FFT) is performed on the image data by FFT unit 108. As discussed above, performing the FFT on the horizontally averaged image data from step 308, the results will be as shown in Figure 6, for example (where the line frequency is 60Hz). It is to be noted that as long as there is enough data to resolve 120Hz, then 100Hz may also be resolvable. Operation will then continue with step 312.

In step 312, the value of the FFT on the 100Hz value is compared with the value at 120 Hz value. In step 314, detector unit 110 determines whether the value for the 60Hz value (i.e., the 120 Hz value which is used for Nyquist resolution), or the 50Hz value (i.e., the 100 Hz value which is used for Nyquist resolution), is larger. In one embodiment, if both the 60Hz value and the 50Hz value are within 10% of each other, then it is assumed that the camera is operating under incandescent light. Operation will then continue with block 316.

It is to be noted that the use of the FFT is an algorithmic optimization, not a requirement. A discrete fourier transform may also be used in other implementations. The benefit of performing a discrete fourier transform is that one is not restricted to choosing a data set which consists of a power of two number of values even though the discrete fourier transform is more computationally intense than the FFT, it solves a particular problem, that of frequency smear.

When a digital time domain to frequency domain transform is performed, the input data will alias if the Nyquist sampling criteria is not met. There is a similar problem with the output spectra, where if the frequency in the data set is "between" two digital frequency values, frequency aliasing occurs, and the resulting spectrum appears smeared out. To avoid frequency smear, the discrete fourier transform may be used at the cost of additional

computation. As the detection only has to be done once to determine the initial lighting conditions, it may be acceptable to use a more computationally intensive algorithm. The choice is a tradeoff between computation time and discrimination accuracy, but the use of the fast-Fourier-transform is not a requirement.

In step 316, based on the determination by detector unit 110 of whether the camera is operating under 60Hz, 50Hz, or incandescent-like conditions, integration time is set according.

Once the flicker frequency has been determined in step 314, detector unit 110 will output a signal that, in one embodiment, represents the flicker frequency. In another embodiment, detector unit 110 will output a signal that signals whether an incandescent, 50Hz, or 60Hz lighting system has been detected. If the light source is a non-flickering source, this would have been determined in step 314, above. The capture control unit then determines the proper integration time for the detected frequency.

In certain configurations, detector unit 110 determines the proper integration time based on the detected flick frequency. Then, detector unit 110 controls capture control unit 106 to capture at the determined frame rate. Thus, the implementation of the control of the frame rate capture can be done in several ways and not limited to a particular embodiment.

By outputting the actual frequency of the oscillation of the light source intensity, the present invention is not limited to eliminating flicker effects from captured video only in 50Hz or 60Hz systems. For example, in some extreme low light situations, where the only light source that is provided is from a user's computer monitor, flicker effects can be eliminated if the system outputs the actual frequency of the light detected. This is because most monitor have a refresh rate that begins from 60Hz. For example, if a scene is illuminated from a monitor that has a refresh rate of 75Hz, the camera has to be able to synchronize the video frame capture to the refresh rate of the monitor.

While the present invention has been particularly described with reference to the various figures, it should be understood that the figures are for illustration only and should not be taken as limiting the scope of the invention. Many changes and modifications may be made to the invention, by one having ordinary skill in the art, without departing from the spirit and scope of the invention.

CLAIMS

What is claimed is:

1. A method comprising the steps of:
 setting a first frame rate;
 setting a capture integration period to a first integration period;
 capturing a set of frames under an illumination source with a first frequency; and,
 determining said first frequency of said illumination.
2. The method of claim 1, further comprising the step of setting said capture integration period to a second integration period based on said first frequency.
3. The method of claim 2, where said step of setting said capture integration period comprises the steps of:
 choosing a set of integration periods based on said first frequency; and
 determining said second integration period from said set of integration periods.
4. The method of claim 3, where said set of integration periods is chosen to substantially reduce any effects from said illumination source.
5. The method of claim 1, where said step of determining said first frequency of said illumination comprises the steps of:
 generating a set of row averaged data comprising an average row image data value for each row of image data in each frame of said set of frames;
 performing a transformation on said set of row averaged data; and;
 detecting said first frequency from said transformation.

6. The method of claim 5, where said transformation is a fast-fourier-transform.

7. The method of claim 1, where said first frequency is substantially at 60Hz.

8. The method of claim 1, where said first frequency is substantially at 50Hz.

9. The method of claim 1, where said first frequency is substantially at 0Hz.

10. An apparatus comprising:
an image sensor; and,
a capture control unit coupled to said image sensor configured to:
set a first frame rate;
set a capture integration period to a first integration period;
capture a set of frames under an illumination source with a first frequency using said image sensor; and,
determine said first frequency of said illumination.

11. The apparatus of claim 10, where said capture control unit is further configured to set said capture integration period to a second integration period based on said first frequency.

12. The apparatus of claim 11, where said capture control unit is configured to set capture integration period by being configured to:
choose a set of integration periods based on said first frequency; and
determine said second integration period from said set of integration periods.

13. The apparatus of claim 12, where said capture control unit is configured to choose said set of integration

period so as to substantially reduce any effects from said illumination source.

14. The apparatus of claim 13, where said capture control unit is configured to determine said first frequency of said first illumination by being configured to:

generate a set of row averaged data comprising an average row image data value for each row of image data in each frame of said set of frames;

perform a transformation on said set of row averaged data; and;

detect said first frequency from said transformation.

15. The apparatus of claim 14, where said transformation is a fast-fourier-transform.

16. The apparatus of claim 10, where said first frequency is substantially at 60Hz.

17. The apparatus of claim 10, where said first frequency is substantially at 50Hz.

18. The apparatus of claim 10, where said first frequency is substantially at 0Hz.

19. An apparatus comprising:

an image sensor;

an analog-to-digital processor coupled to said image sensor;

a flicker detector coupled to said analog-to-digital processor; and,

a capture control unit coupled to said flicker detector and said image sensor.

20. The apparatus of claim 19, where said flicker detector comprises:

a buffer and processing unit coupled to said analog-to-digital processor;

a fast Fourier transform unit coupled to said buffer and processing unit; and,

a detector unit coupled to said buffer and processing unit and said fast Fourier transform unit.

U.S. : 348/349, 296, 350, 364, 365, 367; 354/408, 432

Documentation searched other than minimum documentation to the extent that such documents are included in the fields searched

Electronic data base consulted during the international search (name of data base and, where practicable, search terms used)

APS: "cameras or imagers" and "flicker detection"

C. DOCUMENTS CONSIDERED TO BE RELEVANT

Category*	Citation of document, with indication, where appropriate, of the relevant passages	Relevant to claim No.
X, P	US, 5,495,313 A (KAI) 27 February 1996, column 6, lines 25-68; column 8, lines 1-43; column 11, lines 5-47.	1-20

☐ Further documents are listed in the continuation of Box C. ☐ See patent family annex.

* Special categories of cited documents:	*T* later document published after the international filing date or priority date and not in conflict with the application but cited to understand the principle or theory underlying the invention
A document defining the general state of the art which is not considered to be of particular relevance	*X* document of particular relevance; the claimed invention cannot be considered novel or cannot be considered to involve an inventive step when the document is taken alone
E earlier document published on or after the international filing date	*Y* document of particular relevance; the claimed invention cannot be considered to involve an inventive step when the document is combined with one or more other such documents, such combination being obvious to a person skilled in the art
L document which may throw doubts on priority claim(s) or which is cited to establish the publication date of another citation or other special reason (as specified)	*Z* document member of the same patent family
O document referring to an oral disclosure, use, exhibition or other means	
P document published prior to the international filing date but later than the priority date claimed	

Date of the actual completion of the international search

27 AUGUST 1999

Date of mailing of the international search report

28 OCT 1999
